

What's Wrong With This Tree?

by Robert E. Gough, MSU Professor of Horticulture and Cheryl Moore-Gough, MSU Extension Horticulturist, retired

How to avoid and diagnose problems not caused by disease or insects in newly transplanted or long-standing trees.

MT199518AG Reviewed 3/11

DISEASES AND INSECT ATTACKS AREN'T THE ONLY

killers or even major killers of ornamental trees in Montana – physiological stress is the greatest hazard. Here are some guidelines for diagnosis and prevention of physiological problems leading to severe plant stress and death.

Newly planted or transplanted trees

Plant trees adapted to the area

Select tree species adapted to your area. A reputable local nurseryman or your county Extension agent can help you choose the right plant. MSU Extension Bulletin #123, Tree & Shrub Selection Guide, is also a valuable guide for selecting the right landscape plants. Its sister publication, EB162, will show you how to care properly for the plants you select.

Consider winter hardiness and other factors such as soil type, pH, and salinity. Salty, alkaline soils in eastern Montana limit the number of species to choose from. Other plants, especially dryland species, suffer from the poor soil drainage and poor aeration found in low lying areas with clay soils. Red- and yellow-twig dogwoods, willows, maples, cottonwoods and mountain ash must be planted in areas with moist soil conditions or be provided with ample supplemental irrigation. High elevation also limits plant selection due to the short growing season and cold winter temperatures.

Planting the wrong tree in the wrong spot is a waste of time and money (Figure 1).

Transplant shock

Established plants growing under adequate cultural conditions develop a balance between leaf area and root volume. This assures an adequate supply of water and nutrients for sustained growth. Typically, the root system extends well beyond the spread of the branches and a considerable portion of the roots are cut when the tree is moved. Transplanted to a new location, the plant has the same number of leaves to support with a smaller root system to supply water and nutrients.

FIGURE 1. Many conditions can cause this all-too-common sight.

Symptoms of transplant shock are obvious in trees moved in full leaf or in leaves formed immediately after transplanting. These leaves wilt and if corrective steps are not taken, may eventually turn brown and drop. Needles of evergreens develop a pale green or blue-green color followed by browning and dropping. Symptoms appear first on the youngest leaves which are more subject to desiccation.

To reduce transplant shock, plant bare root plants when they are dormant.

Sprinkle water on leaves to cool them and reduce water loss from their surfaces. Anti-transpirant sprays such as *WiltPruf* or *Foli-Gard* are also effective in reducing water loss. These materials are latex- and wax-based. Though they reduce water loss, they also temporarily interfere with food production within the leaf. Do not overuse these antidesiccants and always follow label directions.

FIGURE 2. Tree must be dug with roots in proper alignment.

Poor digging and handling

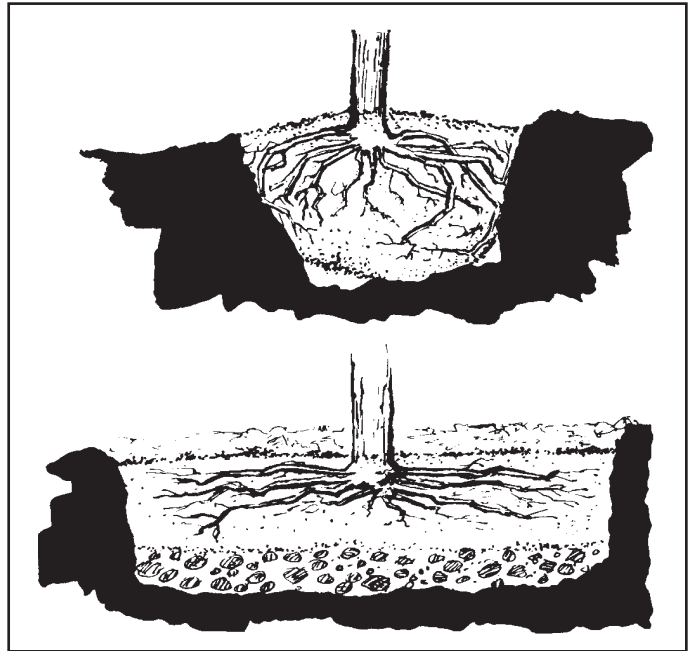

Improper digging can result in an inadequate root system and greater transplant shock. This is the result of excavating too little soil or misalignment of the root ball with the root mass (Figure 2). In general, allow 12 inches of root ball diameter for every inch of trunk diameter measured 12 inches above the soil line. These guidelines are for nursery-grown plants; increase the size of the root ball for native plants or for those not previously transplanted or root pruned.

Plants dug without soil (bare root) **must be transplanted without leaves!** Moving trees in full leaf severely stresses the plant. A continuing demand for water when roots have poor contact with the soil causes extra stress. Further, plants grown in containers or dug with a ball of soil (balled and burlapped, or B&B) must be handled with care to avoid dislodging the roots from the soil ball. When handled properly, container grown or B&B trees suffer much less transplant shock than bare-root plants.

Roots of bare root plants **must be kept moist** until planting, especially those like birch that have fine, fibrous roots. Exposure of roots to the sun and air for as little as one minute can result in up to 50 percent mortality of the fibrous roots! If you must keep bare root plants out of the soil for some time, place them in the shade with the root systems packed in damp sawdust, soil, or other moist media. Ideally, dig and transplant a tree on a cool, cloudy day. Even better, do it in the rain.

Tree roots can be killed by winter temperatures as high as 15°F. Even at higher temperatures, winds can dry the root ball. **Never** leave plants laying on the soil surface with roots exposed to drying winds and cold temperatures. Even plants in containers can be root-damaged by exposure to cold temperatures or to bright summer sun.

FIGURE 3. Roots should have ample room to spread in all directions.

Poor planting techniques

Dig the planting hole to a width and depth adequate to avoid cramping the roots. Give them ample room to spread radially in all directions (Figure 3). Ensure good root-soil contact by pulverizing the planting soil. Encourage root growth into the parent soil by minimizing or eliminating the use of soil amendments such as peat moss and compost.

Do not trample the soil around the roots as you backfill the hole. This could break roots and form air pockets. Instead, settle loose soil around the roots with slow-flowing water from a hose. This eliminates air pockets, doesn't damage roots, and provides complete initial watering. Using B&B or container grown plants reduces backfilling problems at planting time.

After planting, no staking is necessary for trees with limbs close to the ground. Stake bare-root and larger B&B trees to keep wind sway from damaging newly formed roots (Figure 4). Use either single or multiple stakes. There are several stake and tie systems available. Ties should be loose enough to allow for slight movement of the tree. This movement strengthens the tree and helps it develop proper taper. Remove stakes after one year. Trees staked for longer periods become weakened and will not withstand strong winds.

Established Trees

Fall freeze damage

Plants growing actively in the fall can be damaged by unseasonably early cold periods when temperatures drop into the low 20s or high teens. This type of damage occurs before the plant has become dormant as evidenced by development of fall leaf color and normal leaf drop. The extent of damage ranges from some or all leaves remaining

dead on the tree until spring with no twig damage, to death of entire twigs along with the leaves present at time of the freeze. The extent of damage depends upon the duration and depth of the cold spell and upon what stage of growth the tree was in when the cold happened.

Proper fall care of trees usually reduces such damage, except in unseasonably cold seasons. Withholding water, fertilizer, and heavy pruning in the early fall encourages trees to prepare for winter. However, extreme drought can interfere with a tree's acclimating for winter. To fill the tree's water reserves for winter, water only after the leaves have begun to turn color and drop. Continue watering deeply once each week until the soil freezes. Most mature tree and shrub species concentrate their feeder roots in the upper 10 to 12 inches of soil. Therefore, strive to keep this soil volume moist during fall watering.

Tissue at the base of branches, in the branch crotch, and at the base of the tree is last to acclimate to cold. If very low temperatures occur in late fall or early winter these areas may be damaged.

Winter desiccation

Winter desiccation occurs when winter sun and wind cause excessive water loss from the twigs and leaves, while roots in frozen soil are unable to replace it. The problem is most severe in evergreens which maintain their large leaf areas during winter. Look for death of twigs and leaves on the windward side or on the side facing the afternoon sun. Symptoms may be more severe in recently transplanted plants that have not yet re-established a complete root system.

FIGURE 4. Newly planted trees should be staked to prevent wind sway from damaging newly formed roots.

FIGURE 5. Shading the southwest side of the tree trunk can help prevent sun scald.

The best line of defense against winter desiccation is to water all trees and shrubs prior to soil freeze. In addition, winter watering during extended thaw periods when the soil is not frozen is also good practice. Wind and sun barriers such as that illustrated in Figure 5 are helpful for small and newly transplanted trees. **Do not** cover the plants entirely with the barrier, and never place plastic garbage bags over the plants. Air inside these bags can warm to dangerous levels on bright winter days. You can also spray plants in late fall with a film type (latex or wax) antidesiccant to reduce moisture loss from twigs and needles.

Sunscald

Bark on the south and southwest sides of tree trunks and in branch crotches may be killed by sunscald, a particularly prevalent problem in Montana in late winter and early spring. Bark is warmed and the cells dehardened by afternoon sun. Rapid temperature drop after sunset then kills the cells and bark. Damage is most common on smooth-barked trees such as mountain ash, apple and maple, on trees with dark bark, such as cherry, and on young, thin-barked trees. Shrubs and evergreen trees are rarely affected.

There are several ways to reduce sunscald. Tree wrap, such as that made from heavy kraft paper, can be applied to the trunk in October to reflect the sun and reduce abrupt temperature fluctuations (Figure 6). This also helps keep rodents from feeding on the bark. Remove the wrap in April. White latex paint also reflects the sun and prevents rapid temperature changes. Wrap or paint the trunks from the soil line to the lowest branch. The purpose of tree wraps is not to keep the trunk warm but instead to keep it cool. Evergreen shrubs interplanted with trees help shade the tree bark during winter and reduce sunscald.

Frost cracking (shakes)

Extremely rapid temperature changes in the bark and wood cause tree trunks to split vertically. As with sunscald, the bark and wood on the sunny side of the tree warms during the day. If a cold front moves in with a dramatic temperature drop, say from 30°F to -20°F in a very short time, uneven rapid contraction of the wood causes it to crack.

Damage is most common in hardwood trees such as green ash. Trees usually heal the cracks rapidly. However, once cracked, trees will likely crack again along the same line in similar situations. No practical method is available for preventing shakes, which apparently cause no long-term detrimental effects.

Winter freeze damage

Plants are subject to branch, twig, and trunk damage during winter thaws when temperatures remain in the 60 – 70°F range for a week or more. By about Jan. 1 trees have usually satisfied their chilling requirements and can begin to grow when conditions are favorable. Hence, a thaw period

mimics springtime conditions. Water flows back into cells, the tissue deacclimates to cold temperatures, and the plant becomes susceptible to freeze damage if temperatures drop rapidly back to seasonal normals. If the change is gradual, even over two to three days, tissue can reacclimate to colder temperatures and damage may not occur. Plants affected by winter freezes can be so damaged that only the main trunk and scaffold branches are viable in the spring. Young trees can be killed to the snow line or the soil line.

Sometimes, patches of bark on limbs and trunks are killed by cold temperatures. The affected area first appears purplish or dark and often somewhat sunken. Eventually, the bark dries, cracks, and can peel from the area. Unlike sunscald, this injury is not limited to the southwest side of the tree. Tack the bark back into place if it is still alive. Cover the seams with tree wound dressing to reduce desiccation. If it's dead, remove it completely and allow the wound to heal. Do not cover this wound with dressing.

Prolonged, severe winter cold when there is no snow cover can kill plant roots. Even acclimated roots can be killed when soil temperatures drop to 10° to 15°F. Snow or mulch protects the tree against this type of damage. Trees with damaged roots usually start growth in spring, but the leaves will be small and both leaves and flowers are likely to wilt shortly after bloom. The tree may die rapidly in summer or may die slowly over a period of years if only a portion of the root system was killed. The tree may recover if the root system was damaged only slightly.

An unusually rampant growth of suckers from the base of the tree is a common symptom of winter freeze damage. The top of the tree may have suffered severe tissue damage and the suckers are the tree's way of trying to reestablish a top quickly to balance and maintain the large root system. Attempts to train suckers into becoming a replacement for the original tree are seldom entirely satisfactory.

Spring frosts

Spring frosts are usually most damaging to flower buds, flowers and young fruit, but can injure tree bark as well. Trees may produce no flowers or fruit but will otherwise

FIGURE 6. Special tape helps prevent sun scald and can deter rodents.

look healthy. Often, only a few degrees of warmth for a short period on one or two nights are needed for protection. If you have only one or two young flowering trees, hang a 150 watt infrared heat lamp over them with the rays directed onto the tree. This is most effective on calm nights.

Excess soil moisture

Trees develop roots at certain soil depths according to soil oxygen levels. Continuously high soil moisture from poorly drained soils or excessive irrigation can cause “wet feet.” Roots are damaged and the plant's ability to absorb water and nutrients is reduced. Under these conditions, the tree develops enlarged lenticels on the bark near the trunk base and forms new roots close to the soil surface. Often the deeper, older roots rot away. This makes the tree more subject to wind throw. Removal of the unsightly surface roots can severely damage the growth of the tree.

Montana's trees are continually stressed by the environment. Even if direct damage does not occur, indirect damage in the form of increased frequency of attacks by insects and diseases can weaken the tree over time. Trees are expensive and valuable – do all you can to keep them healthy.
